ABSTRACT

The paper is a brief retrospective review of our contribution to the Si:Er problem in the last decade. It contains a description of the experimental facilities, results of the light emitting media (Si:Er and Si1-xGex:Er) research and device applications.

INTRODUCTION

The idea to use silicon as the host matrix for electrical and optical excitation of Er3+ ions embedded into it [1,2] proved rather fruitful in terms of solving the problems involved in silicon optoelectronics. The use of silicon as an intermediate medium transferring the excitation induced by the current or optical pumping to Er3+ ions has allowed a substantial increase of the excitation cross-section (up to 3·10^{-15} cm² [3]), i.e., by 5-6 orders as compared with direct optical excitation of Er3+ embedded into a dielectric matrix (8·10^{-21} cm² [4]).

The progress in the development of Si:Er-based light-emitting devices with a higher power yield and quantum efficiency is associated with the improvement of the optically active media (increase of optically active Er3+ concentration, formation of optically active Er-containing complexes with higher excitation cross-section and minimization of Er3+ nonradiative relaxation processes) and optimization of the light emitting devices design. In this contribution we focus on both approaches: i) we report a new optically active Er-containing complex radiating at 1.54 μm, a novel mechanism of sub-band-gap photo-excitation of erbium in silicon; ii) show possibilities to enhance the power yield of electroluminescent light emitting devices (LEDs) including LEDs radiating at reverse and forward bias of the p-n junction, demonstrate a novel long-term optical memory effect on the basis of Si:Er light emitting structure with the active Si:Er layer placed within the depletion region, discuss the perspectives and progress in the development of laser-type structures on Si:Er basis; iii) develop an original sublimation variant of the MBE technique (SMBE) and demonstrate its capabilities for realizing light-emitting devices effectively radiating up to room temperature.

STRUCTURE GROWTH AND CHARACTERIZATION

The light emitting structures and devices considered in this contribution were grown with an original SMBE technique that is basically a modification of the standard MBE in which fluxes of...
Si and doping impurities (Er in the case in question) are produced by sublimation of a Si crystal intentionally doped with these impurities [5]. The SMBE technique successfully combines a fairly high growth rate (up to 5 µm/hour) with a high crystalline quality of epitaxial layers and a precise control of the impurity profiles (including the possibility for delta doping). Its merits have been experimentally demonstrated in the last decade through realization of a variety of Si:Er-based light emitting structures and devices, such as thick uniformly doped Si:Er layers (up to 3-5 µm); periodic multilayer …Si/Si:Er/Si/Si:Er/Si… structures (Si and Si:Er layers thickness down to 10-20 Å, the number of periods up to 400) with the quantum efficiency of more than 10 % at 4.2K and pump power of 10 µW; light emitting diodes (LEDs) radiating at reverse bias under the p-n junction breakdown (from tunnel through mixed to avalanche regimes) at room temperature [6-9].

Most Si:Er-based light emitting structures and devices were grown on p- and n-type Si (100) substrates with the resistivity of 10-20 Ω⋅cm. The growth temperature (T_{gr}) was varied from 430 to 700°C. The Er and O concentrations in Si:Er layers were of about (3-5) \cdot 10^{18} and (1-10) \cdot 10^{19} cm^{-3}, respectively. The number and types of simultaneously sublimating sources were varied depending on the desired features of growing layers. SMBE allows growth of epitaxial structures with the layer thickness and carrier concentration continuously varying along the substrate length. It eventually makes it possible to produce series of LEDs with smoothly varying parameters in a single growth cycle, which is essential in a new LED design engineering. SMBE allows a separate control of the erbium and donor concentrations in Si:Er layers, which makes it easier to control the breakdown regime of LEDs.

To characterize the Si:Er and SiGe:Er layers, we use the standard methods of secondary ion mass spectrometry (SIMS), Rutherford backscattering spectrometry (RBS), X-ray diffraction, capacitance-voltage (CV) measurements, admittance spectroscopy, DLTS and the Hall effect. The major part of the photo- (PL) and electroluminescence (EL) studies was carried out using the high resolution BOMEM DA3 Fourier spectrometer and the grating monochromator MDR-23. The PL spectra were excited with an Ar^+ -ion laser, the EL spectra with a pulse or continuous drive current. Liquid nitrogen cooled Ge and InGaAs detectors were used for detection of the luminescence signal. Mesa-like LEDs were formed using the conventional mesa technique. The fabricated diodes had the radiating area of up to 2.5 mm², 70 % of which was free of the metal cover.

NEW OPTICALLY ACTIVE Er-1 CENTER IN SMBE-GROWN Si:Er/Si STRUCTURES

Depending on the T_{gr}, the PL intensity and excitation efficiency of SMBE grown Si:Er structures are governed by different types of optically active Er centers. At a relatively low T_{gr} of about 430°C, the series of low symmetry Er centers identified earlier in highly O and Er implanted Si [10] dominate in the PL spectrum (lower curve in figure 1). Most pronounced at this temperature is the axial symmetry Er complex with oxygen, the well-known center Er-O1 (marked by arrows in figure 1). With an increasing T_{gr} a fairly broad spectral band (FWHM = 20 - 30 cm^{-1}) is seen to develop. It was interpreted as pertaining to Er^{3+} ion in SiO2-like precipitates [10]. At the T_{gr} of 560°C the PL spectrum, together with the dominance of the SiO2-precipitate type Er centers, exhibits formation of a new Er-related center, the center Er-1 (marked by arrows in figure 1). In our previous publications we distinguished the center Er-1 as specific and one of the most optically efficient among the variety of Er-related centers discovered in SMBE structures [11, 6]. Besides being formed at an elevated T_{gr}, it emerges also as a result of the transformation of erbium-oxygen complexes during the 800°C annealing of Si:Er layers grown at 430°C. In the last case, the luminescent response of Si:Er samples is governed mainly by this isolated center Er-1 with the characteristic spectral line pattern consisting of eight very well resolved PL lines (see figure 2 and the upper curve in figure 1).
The ultra small line widths and high intensity of the Er-1 PL spectrum made possible a successful observation of the Zeeman effect [12]. A detailed analysis of the magnetic field induced splitting [13] confirmed that, indeed, the Er-1 PL emission is related to a particular type of Er center dominant in the structure under study. Based on the analysis of the magnetic field induced angular dependent splitting of the PL lines, we identify the orthorhombic-I symmetry of the Er-1 center and find $g$-tensors for several lower-lying levels of the $^4I_{15/2}$ ground and the lowest excited $^4I_{13/2}$ state multiplets.

**Figure 1.** PL spectra of the uniformly doped SMBE layers grown at different temperatures. The upper curve represents the spectrum of Si:Er layer grown at 430°C after subsequent annealing at 800°C for 30 min in hydrogen atmosphere.

The ultra small line widths and high intensity of the Er-1 PL spectrum made possible a successful observation of the Zeeman effect [12]. A detailed analysis of the magnetic field induced splitting [13] confirmed that, indeed, the Er-1 PL emission is related to a particular type of Er center dominant in the structure under study. Based on the analysis of the magnetic field induced angular dependent splitting of the PL lines, we identify the orthorhombic-I symmetry of the Er-1 center and find $g$-tensors for several lower-lying levels of the $^4I_{15/2}$ ground and the lowest excited $^4I_{13/2}$ state multiplets.

**Figure 2.** PL spectrum of SMBE grown multilayer Si:Er/Si structure with predominant Er-1 center. The inset shows a high-resolution spectrum of the highest-intensity $L^1$ line in the Er-1 series.
In particular, we identify the original $\Gamma_6$ and $\Gamma_7$ characters for the lowest crystal-field split levels of the ground and the excited states, respectively. Based on this analysis, we suggest that the microscopic structure of the Er-1 center comprises a single Er$^{3+}$ ion at a distorted interstitial $T_d$ site with multiple oxygen atoms in its direct vicinity.

Realization of preferential generation of only one type of optically active Er-related centers, which is feasible by appropriate annealing of the SMBE grown Si:Er/Si multianolayer structure, is a major step forward to Si photonics based on Er doping. As can be seen in figure 2, the width of this PL line is extremely small, $\Delta \lambda \leq 0.08$ cm$^{-1}$ (10 µeV). To the best of our knowledge, this is among the lowest values ever measured for any emission band of RE ions in a semiconductor matrix. We have established that the spectral characteristics of emission related to the Er-1 center (intensity and linewidth) indicate a feasibility of a $10^3$ higher value of the absorption cross section, as compared to the implanted Si:Er materials used so far. Therefore, the Er-1 center emerges as a plausible candidate for realization of the optical gain in Si: Er.

SUB-BAND-GAP PHOTOEXCITATION OF ERBIUM IN SILICON

The excitation spectra of erbium PL in SMBE-grown Si:Er structures have been taken using Nd:YAG-pumped optical parametric oscillator in a wide range of excitation wavelengths ($\lambda_{ex} =$ 780 - 1500 nm) [14]. It has been shown that a considerable signal of erbium PL can be obtained with the excitation photon energies lower than the band gap of Si ($\lambda_{ex} > 1060$ nm) (figure 3). Moreover, at a high pumping power a rapid increase of the Er luminescence intensity has been observed in the range $\lambda_{ex} =$ 1000 - 1030 nm, which corresponds to the edge of light absorption in bulk silicon. At the same time a strong decrease of the band-to-band PL intensity took place in this wavelength range. As could be expected, no noticeable signal of the band-to-band PL was observed at excitation photon energies below the Si band-gap. This drop in the exciton PL intensity is associated with the decrease in the absorption coefficient of silicon in the wavelength region in question and, as a consequence, the decrease in the intensity of electron-hole pair generation. On the other hand, this result evidently indicates that under conditions of sub-band-gap pumping excitation of the erbium ions must proceed without participation of excitons.

From the obtained experimental data and, in particular, from the high efficiency of Er PL, we can conclude that for $\hbar \nu_{ex} < E_g$ the absorption occurs in the epitaxial erbium-doped layers. The

![Figure 3](https://www.cambridge.org/core/core/terms, https://doi.org/10.1557/PROC-866-V1.4)

**Figure 3.** Erbium- and exciton-related PL excitation spectra of SMBE Si:Er structure and a possible mechanism of sub-band-gap excitation ($\hbar \nu_{ex} < E_g$) of erbium in silicon.
observation of sub-band-gap excitation of erbium PL can be explained assuming that the Er-related
impurity levels in the silicon band gap are formed in the epitaxial layers. Indeed, erbium-doped
silicon layers are known to demonstrate, as a rule, the n-type conductivity. In such a case, the
absorption of a photon of energy $h\nu_{ex} < E_g$ could promote electrons from the valence band directly
to the donor levels associated with erbium. Subsequent nonradiative recombination of these electrons
with holes in the valence band could deliver energy necessary for excitation of Er ions. The proposed
mechanism is schematically depicted on figure 3.

The proposed mechanism of erbium ion excitation can also account for the increase in the
erbium PL intensity at longer excitation wavelengths, as experimentally observed in the range
$\lambda_{ex} = 1000 - 1030$ nm. The band-to-band pumping of Si:Er structures generates a large number
electron-hole pairs, which gives rise to the onset of intense, free-carrier-mediated nonradiative Auger-
deexcitation of Er ions, thus substantially lowering the efficiency of erbium PL. As the pump photon
energy decreases, the light absorption coefficient in bulk silicon drops sharply in the vicinity of $E_g$,
which leads to a sharp drop in the number of free carriers created in the structure. Therefore, the
Auger deexcitation efficiency decreases strongly, thereby increasing the erbium PL signal.

LIGHT EMITTING DIODES RADIATING AT MIXED BREAKDOWN REGIME

Two types of the p-n junction design were investigated [9,15]. The first type are dominating
$p^+\text{-Si}/n-\text{Si}:\text{Er}$ LEDs in which the thickness of the n-Si:Er layer exceeds the width of the space charge
region (SCR) at any reverse bias including the breakdown voltage $U_{br}$. In these diodes $U_{br}$ and the
breakdown mechanism are determined by the donor concentration $N_D$ in the n-Si:Er layer (left inset
to figure 4). A decrease of the donor concentration $N_D$ stimulates an increase of $U_{br}$ and transformation
of the breakdown mechanism from tunnel ($U_{br}^{77} > U_{br}^{300}$) through mixed ($U_{br}^{77} \approx U_{br}^{300}$) to avalanche
($U_{br}^{77} < U_{br}^{300}$). The second type are LEDs which are not widely adopted in Si:Er applications. They
are $p^-\text{-Si}/n^-\text{-Si}:\text{Er}/n^+\text{-Si}$ LEDs in which a thin low doped n^-Si:Er layer ($N_D \sim 10^{16}$ cm$^{-3}$) is placed

![Figure 4](https://www.cambridge.org/core/terms). Er$^{3+}$ EL intensity as a function of $U_{br}$ for various types of LEDs. The insets show a change
of the breakdown mechanism with the carrier concentration (left) and n^-Si:Er layer width (right).
between the high doped n⁺-Si and p⁺-Si layers. In these diodes $U_{br}$ and the breakdown mechanism are determined by the thickness of n⁻-Si:Er layer (right inset to figure 4), which is of great interest in itself as another way to control the breakdown mechanism. It is surprising but we observed a pronounced tunnel breakdown at $N_D = 1 \times 10^{16} \text{cm}^{-3}$ and the width of n⁻-Si:Er layer $d < 40 \text{nm}$. The increase of the n⁻-Si:Er layer width stimulates, as in the previous case, an increase of $U_{br}$ and transformation of the breakdown mechanism from tunnel to avalanche.

For both types of LEDs the plot of the erbium EL intensity versus $U_{br}$ looks like an asymmetric bell-shaped curve with the maximum in the region of the mixed breakdown mechanism ($U_{br}^{300} \approx 5-6 \text{V}$, figure 4). EL spectra typical for LEDs with different p-n junction breakdown mechanisms are shown in figure 5. The Er-related EL is presented by the sharp EL line at 1.54 μm, the broad emission band is associated with the intraband radiating transitions of hot carriers in silicon [16]. We observed a decrease in the Er-related EL intensity in LEDs with both tunnel ($U_{br}^{300} < 5\text{V}$) and avalanche ($U_{br}^{300} > 6-8 \text{V}$) breakdown mechanisms, unlike in the mixed LEDs.

The shortcomings of the tunnel diodes, as compared with mixed and avalanche diodes, result from a lower excitation efficiency of Er³⁺ (the product $\sigma \tau$ characterizing the excitation efficiency decreases from $9.4 \times 10^{-20} \text{cm}^2 \text{s}$ in a mixed diode with $U_{br}^{300} = 5.0 \text{V}$ down to $1.4 \times 10^{-20} \text{cm}^2 \text{s}$ in a tunnel diode with $U_{br}^{300} = 2.7 \text{V}$ (figure 5), $\sigma$ and $\tau$ are the excitation cross-section and the lifetime of an excited Er³⁺ ion) and a smaller SCR width and, therefore, Er³⁺ surface density (only Er ions located in SCR are allowed to relax radiatively, since a strong nonradiative Auger deexcitation of Er³⁺ ions with free electrons occurs outside SCR). The shortcomings of the avalanche diodes are connected with the non-uniform distribution of the drive current density over the p-n junction area, which eventually leads finally to the microplasma breakdown. So we conclude that Si:Er LEDs operating in the mixed breakdown conditions provide an optimum combination of high Er³⁺ EL intensity and excitation efficiency with the uniformity of the p-n junction breakdown and seem to be more preferred for reaching maximal Er³⁺ EL intensity at room temperature.

We have made EL kinetic measurements for LEDs radiating at mixed breakdown regime to estimate the excitation cross-section, the lifetime of Er³⁺, and the internal quantum efficiency. The respective values came to $\sigma \approx 1.4 \times 10^{-16} \text{cm}^2$, $\tau \approx 540 \mu\text{s}$, $\eta \sim 10^{-3}$ [17].

![Figure 5](image-url). (a) EL spectrum versus LED breakdown mechanism. For clearness the spectra are moved along the abscissa and ordinate axes. The spectra were taken at 300 K and drive current density of 8 A/cm². (b) The dependence of $\sigma \tau$ production on the breakdown voltage.
Note that the erbium EL intensity in $p^+/n^-/Si:Er/n^+/-Si$ structures is noticeably lower than that in $p^+/Si/n^-/Si:Er$ structures. In our opinion, the reason is as follows. An impact excitation of Er$^{3+}$ with hot electrons is most effective, if the electrons energy $W$ is not too high. It should satisfy the condition: $W_{th1} < W < W_{th2}$, where $W_{th1} \approx 0.8$ eV is the Er$^{3+}$ excitation energy (the $^4I_{13/2} \rightarrow ^4I_{15/2}$ transition) and $W_{th2} \sim 1.5$ $E_G$ ($E_G$ is the band-gap width in silicon) is the energy at which an intense avalanching begins in the SCR. Evaluations show that the flow of electrons with energies in the range $W_{th1} < W < W_{th2}$ forms mainly in that part of SCR where the electric field is rather weak; there is no such region in $p^-/Si/n^-/Si:Er/n^+/-Si$ diodes but it exists in $p^-/Si/n^-/Si:Er$ diodes. We believe the Er$^{3+}$ impact excitation to be more effective in so-called tunneling transit-time diode structures of the $p^-/Si/n^-/Si:Er$ type. The narrow $p^-/Si/n^-/Si$ junction (the strong-field region) should act as a tunneling injector of hot electrons with energies of $W_{th1} < W < W_{th2}$. The wide enough $n^-/Si:Er$ layer (up to 0.5-1 µm) represents a weak-field region, which is needed to excite Er ions and compensate for the energy loss due to scattering by the optical phonons. Our precomputations show that such light emitting structures may prove quite promising for reaching maximal Er-related EL intensity at room temperature.

**LEDs ON THE BASIS OF SELECTIVELY DOPED MULTILAYER STRUCTURES**

As we reported, among the advantages of the SMBE method is a capability for growing structures with desired, even $\delta$, doping profiles. Here we show that by a proper design of an impurity distribution profile one can substantially increase the EL power yield of a Si:Er-based light emitting structure. We examine here two LEDs radiating at 80 K under the forward bias of $p-n$ junction. The first one is produced on the basis of a selectively doped Si:Er multilayer structure. Its active region consists of 52 periods of alternating Si:Er and undoped Si layers. The thicknesses of the Si:Er and Si layers are 70 and 120 Å, respectively. The second diode is an ordinary LED with the active region provided by a Si:Er layer with a thickness of 1.6 µm uniformly doped with Er. The Er concentration in Si:Er layers of both LEDs was about $(3-5)\times10^{18}$ cm$^{-3}$ according to RBS and SIMS measurements.

As shown in figure 6, the EL signal from a multilayer LED saturates weakly with an increasing current density (except for the last few points of curve 1, where the overheating of structure becomes apparent) and at high current densities surpasses the signal obtained in a uniformly doped structure by more than an order of magnitude. Thus, these results clearly show a strong influence of the impurity distribution profile and, in particular, of the presence in the structure of undoped Si layers on Er-

![Figure 6](https://www.cambridge.org/core/terms). https://doi.org/10.1557/PROC-866-V1.4

**Figure 6.** Dependences of the EL intensity on the drive current density for LEDs with an active region selectively (1) and uniformly (2) doped with Er. The inset shows high-resolution EL spectra ($\Delta v = 1$ cm$^{-1}$) of these diodes taken at 80K in the forward bias regime.
related EL efficiency. Roughly, this can be explained by the enhancement of the Er$^{3+}$ excitation efficiency, which is stimulated by the formation in the light emitting structure of undoped Si layers where an intense exciton generation takes place. Note that the same tendency towards an increase in the PL efficiency of multilayer structures as compared to the uniformly doped ones was recorded by us earlier [6-8]. Though the mechanism of this strong increase of luminescence intensity observed in selectively doped multilayer structures needs to be understood in more detail, even now we can expect that the development of LEDs with modified Er impurity profiles will offer new prospects for realization of industrially useful optoelectronic devices.

**ELECTRO-OPTICAL STORAGE ELEMENT**

In this part we present the results of the study of EL of n$^+$-Si/n$^-$-Si/n$^-$-Si:Er/n$^-$-Si/p$^+$-Si structures in which the Er doped active layer was positioned relative to the p-n junction in the SCR. The structures were grown using the SMBE method on a p-Si(100) substrate with the doping level $N_A \approx 10^{17}$ cm$^{-3}$. Nearest to the substrate we grew a layer of pure n-Si of a thickness to 1 µm and the free carrier concentration $n \approx 2 \times 10^{15}$ cm$^{-3}$, then came a thin (about 70 nm) active layer doped with Er$^{3+}$ ions, on which we placed another layer of pure n-Si as thick as 10 µm and an n$^-$ layer with $n \approx 6 \times 10^{18}$ cm$^{-3}$. The concentration of Er ions in the active layer was $\sim 10^{18}$ cm$^{-3}$. The diode structure geometry was chosen such that the Er-doped layer is located within the SCR.

Investigation of the Er$^{3+}$ EL kinetics in a structure with an active layer positioned in SCR revealed a few interesting peculiarities. The novelty here was observation of the electro-optical conversion with a long-term memory effect of the structure about the current pulse flow through the p-n transition at forward bias. A long time after termination of the forward-bias pulse we observed "stored" EL (SEL) of Er$^{3+}$ ions, by application of a reverse bias to the diode structure (figure 7). It is important that in all experiments: i) the voltage of the reverse bias pulses that excite SEL $U_{REV} \sim 10$ V was below the breakdown voltage, so the SEL effect cannot be explained by the EL signal arising at avalanche breakdown of the reverse-biased p-n junction; ii) SEL of Er$^{3+}$ ions was observed only if the reverse bias pulse was preceded by a forward bias pulse.

![Diagram](https://www.cambridge.org/core/terms). https://doi.org/10.1557/PROC-866-V1.4

**Figure 7.** Electro-optical conversion with a long-term memory effect. “Stored” EL (SEL) of Er$^{3+}$ ions has been observed a long time (up to 100 ms) after termination of the forward-bias pulse, by application of a reverse bias $U < U_{breakdown}$ to the diode structure.
The SEL intensity remains stable with an increase of the intervals between the forward-bias and reverse-bias pulses up to the maximal value of 100 ms in our experiments. Dependence of the SEL intensity on the reverse bias pulse parameters shows that with the pulse length decreasing down to the minimal values used in the experiment (~ 10 µs) the SEL amplitude (intensity) did not change. This effect was obtained in our experiments at temperatures up to 120 K.

The experimentally observed peculiarities suggest that the "memory" effect characteristic of the electro-optical conversion is associated with availability in the structure of deep traps for free carriers. During the forward bias pulse the traps fill up with the carriers. At reverse (negative) bias the carriers get free from the traps and are able to excite Er ions by impact excitation, if the electric field is high enough.

In Si based optoelectronics of critical importance are memory elements with an optical output. In a recent publication [18] the authors reported the feasibility of an all optical memory on the basis of Si:Er/Si structures. Just as important is the possibility to electrically control a Si memory element with an optical output. Actually, the structure described in this paper is exactly such a device in which the memory elements are deep traps located in a Si:Er layer. The memory work includes the following stages:

- at forward-bias pulse the deep traps are filled up with carriers (data writing);
- after the pulse terminates the traps can retain their charged state for a long time (data storage);
- application of a short pulse of the reverse bias sets the carriers free and they excite EL of the Er\(^{3+}\) ion (optical output of data);
- by application of a reverse-bias pulse of a small amplitude the carriers are released from the traps without luminescence (memory erasing).

This electro-optical element does not require external sources of radiation; besides, the writing and erasing of information here (filling and depletion of the deep traps) can be effected without exciting the luminescence of an Er ion, which may prove a more convenient option in some applications.

**PROSPECTS OF THE LASER REALIZATION**

As mentioned above, Si:Er/Si structures grown by the sublimation MBE exhibit extremely narrow PL lines (see figure 2). According to our estimations, the optical gain accessible in these structures should reach the value of 3-30 cm\(^{-1}\) [8]. It means that the structures of such type emerge as plausible
candidates for realizing the population inversion and stimulated emission in Si:Er-based materials.

Laser type structures can be developed on the basis of Si/Si$_{1-x}$Ge$_x$:Er/Si heterostructures with the active Si$_{1-x}$Ge$_x$:Er media. The waveguiding effect in this case is achieved through introduction of Si$_{1-x}$Ge$_x$:Er layers, the refractive index of which depends on the Ge content and can be varied in a wide range. Here we present the results of theoretical simulations and experimental studies, obtained for Si/Si$_{1-x}$Ge$_x$:Er/Si heterostructures being developed with a view to implementing this idea. The structures in question were grown by a specific method that combines the principles of sublimation MBE with the growth in gas (GeH$_4$) atmosphere.

Figure 8 shows the results of simulations carried out for the optical mode distribution in Si/Si$_{1-x}$Ge$_x$/Si heterostructure and the mode confinement factor ($\Gamma$) versus thickness ($d$) and Ge content ($x$) of the Si$_{1-x}$Ge$_x$ layer. As follows from this figure, the maximal confinement factor and, hence, the gain can be achieved in the structures with sufficiently thick Si$_{1-x}$Ge$_x$ layers (thicker than 0.5 $\mu$m) and high Ge content (more than 30–40%). The $\Gamma$ factor in this case should reach the value up to 0.98 thus enabling strong localization of the optical modes.

PL studies carried out for Si/Si$_{1-x}$Ge$_x$:Er/Si heterostructures clearly demonstrate their high luminescent efficiency, as compared with Si:Er/Si structures. Figure 9 shows the PL spectra taken in the same experimental conditions for some characteristic Si/Si$_{1-x}$Ge$_x$:Er/Si hetero-structures and for one of the most luminescence-effective Si:Er structures, which has a nearly 0.4% external quantum efficiency at 4.2 K. According to the spectral response, the axial symmetry Er-O1 center is dominating in Si/Si$_{1-x}$Ge$_x$:Er/Si structures. PL signals at 1.54 $\mu$m for both types of structures (Si:Er and Si/Si$_{1-x}$Ge$_x$:Er/Si) are comparable, which points to their high luminescence efficiency. Note that we did not observe any appreciable influence of the strain relaxation taking place in Si$_{1-x}$Ge$_x$ layers, especially at high Ge content and thickness, on the intensity of Er-related PL. Even the fully relaxed structures demonstrated efficient Er-related PL (the residual elastic strain coefficient for the structure represented by the spectrum 3 in figure 9 amounts to 9±10%).

One can demonstrate a possibility to achieve the population inversion of the Er ion states in these structures under optical pumping [19]. This result has been obtained recently for a Si/Si$_{0.72}$Ge$_{0.28}$:Er/Si

![Figure 9. PL spectra of the Si:Er/Si and Si/Si$_{1-x}$Ge$_x$:Er/Si structures. Parameters of the structures: 1 – $d_{Si:Er} = 1.8$ $\mu$m; 2 – $d_{SiGe:Er} = 0.6$ $\mu$m, $x = 11\%$; 3 – $d_{SiGe:Er} = 1.1$ $\mu$m, $x = 28\%$.](image-url)
heterostructure with the parameters optimized towards laser realization ($\Gamma$ factor for TE$_{00}$ mode amounts to 0.94, see also spectrum 3 in figure 9). The occurrence of population inversion was determined from the PL transients measurements carried out at 10 K under Cu-laser excitation ($h\nu_{\text{ex}} = 2.1, 2.4$ eV). By solving the balance equations, one can show that the relative number of Er ions in the excited states $^4I_{13/2}$ is directly related with the ratio of the PL rise and decay times measured for the Er signal:

$$\frac{N^*}{N_{\text{Er}}} = 1 - \frac{\tau_{\text{rise}}}{\tau_{\text{decay}}} \cdot$$

where $N^*$ is the number of Er ions in the excited states, $N$ the total concentration of optically active Er ions, $\tau_{\text{rise}}, \tau_{\text{decay}}$ the PL rise and decay times, respectively.

Dependences of the PL rise and decay times on the pump intensity measured for the Si/Si$_{0.72}$Ge$_{0.28}$:Er/Si structure at the wavelength of Er peak (1.537 $\mu$m) are shown in figure 10 a. With an increase in pump intensity one can see a pronounced decrease of the PL rise times whereas the decay times of the Er signal remain practically unchanged. At the pump intensity of $\sim 1$ W/cm$^2$, the estimations made by the above formula indicate a high population inversion of the Er$^{3+}$ ion states in this structure ($\sim 80\%$ of the total amount of optically active ions are found in the excited states – see figure 10 b). In fact, this last result provides reliable evidence supporting feasibility of a laser on Si:Er basis in near future.

**CONCLUSIONS**

The brief review of our contribution to the Si:Er problem in the last decade is presented. We connect the further progress in this field with new approaches to the design of the Si:Er-based light-emitting devices. Among them we consider LEDs on the basis of selectively doped multilayer structures radiating under forward bias and LEDs with expanded space charge region, including multidiode structures, emitting at the breakdown regime. We believe that an all-silicon laser operating at a 1.54 $\mu$m can be realized on the basis of SMBE grown Si:Er structures with the dominating Er-1 center characterized by extremely narrow PL line (less than 10 $\mu$eV at 4.2 K). At last we suppose that a practically applicable device can be developed on the basis of the observed electro-optical storage effect.
